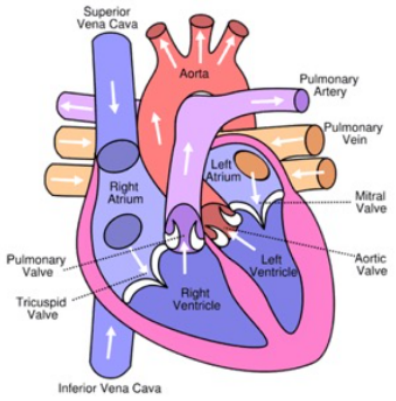
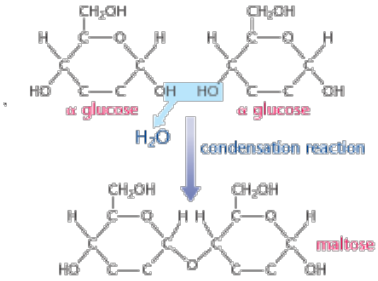
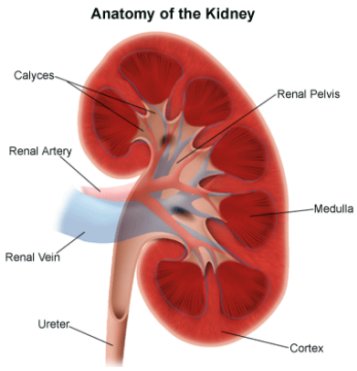
Getting a head start on AS Level Biology







This booklet will provide you with a brief account of the content covered at GCSE and how it crosses over into AS and A2 level. Content will include mostly GCSE content with extension text relating to the A level.

Bring the booklet to your enrolment meeting as evidence of completion – you will hand in to N Rochelle in your first lesson.

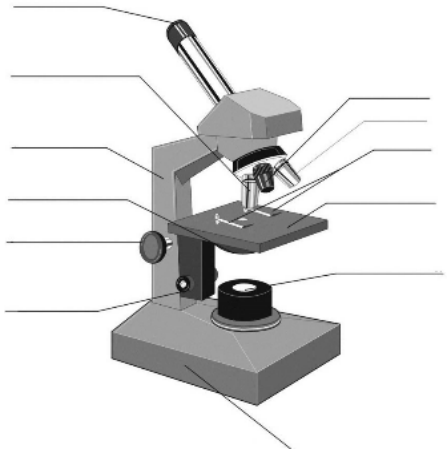
Looking forward to seeing you on the Biology A level course September 2020.

Email any queries to n.rochelle@macademy.org.uk

Microscopes;

The Light microscope allows you to view animal cells. It can magnify up to 1500 times. Some organelles such as mitochondria, chloroplasts, vacuoles, cell walls, cell membranes and nuclei are visible. Staining makes these organelles visible.

Label and annotate the diagram

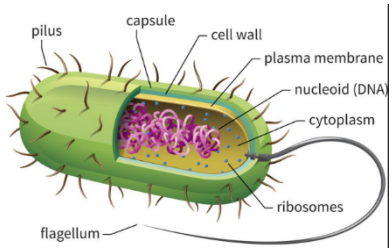


The electron microscope; invented in 1950s it allows a much higher magnification (500 000x) and better resolution, allowing greater detail to be seen. Electron microscopes allowed detailed ultrastructure of the cell to be seen, such as ribosomes and the inside of mitochondria and chloroplasts. The image is called an ELECTRON MICROGRAPH.

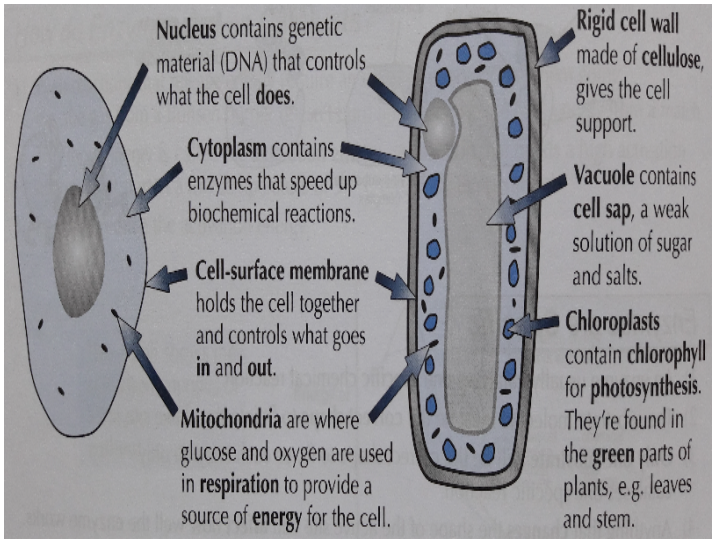
Eukaryotes and prokaryotes;

Prokaryotes are singled celled organisms such as bacteria.

Usually much smaller than eukaryotic cells (1/10th the size), do not contain a nucleus, chloroplasts or mitochondria, DNA can be found floating free in the cytoplasm or in loops called Plasmids, some have flagellum for movement.



Eukaryotic cells are more complex and can be single cellular or multi cellular organisms.



Questions;

Name 3 things visible with a light microscope in both animal and plant cells._____

_____

Name 4 organelles that both plant and an animal cell have. _____

_____

What is the calculation used to calculate the magnification of an object? _____

_____

What is the function of the mitochondria? _____

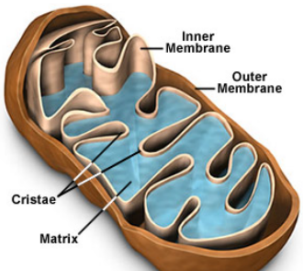
Cell structure;

Nuclei: controls the cell function, containing the DNA which is the coded information for the production of proteins.

During cell division the chromosomes become shorter and thicker and can be seen with a light microscope. The chromosomes will then make a copy of themselves, one copy for each cell produced during cytokinesis.

Nuclei have a double membrane called the nuclear envelope.

Mitochondria: can be seen with a light microscope, however, greater internal detail can be seen using an electron microscope. The mitochondria's function is to carry out aerobic respiration.



The energy released is used to form molecules of ATP.

ATP is used in the cells to provide energy for muscular contractions, active transport as well as anabolic and catabolic reactions.

Cell wall: the plant cell wall is made up of cellulose Molecules laid side by side to form microfibrils.

These provides rigidity and support for the cell.

Questions;

Name 2 molecules that make up the cell membrane.

_____

Describe the membranes of the mitochondria.

_____

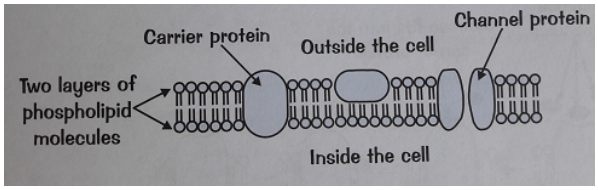
What is the name of the molecule that provide energy to the cell? _____

What term is used to describe water concentration?

_____

Cell structure;

Cell surface membrane: Found around every cell, it allows the movement of substances into and out of the cell. It is a partially permeable membrane and will prevent certain substances from entering.



It is made up of a double layer called the PHOSPHOLIPID BILAYER. These are molecules closely packed together in a mosaic pattern. Within the bilayer are large proteins which are also responsible for transport and for cell recognition.

Transport into and out of cells

There are 4 modes of transport you need to be aware of;

Diffusion; can be gas or liquid particles. They move from an area of high concentration to an area of low concentration down a concentration gradient. Small molecules such as oxygen, water and carbon dioxide can pass through the phospholipid bilayer.

Osmosis; occurs only with water. The water particles move from an area of high water concentration to an area of low water concentration, down a concentration gradient, across a partially permeable membrane. NO ENERGY IS REQUIRED. You will be required to refer to water potential in AS level not water concentration.

Facilitated diffusion; Some particles are too large to fit through the phospholipid bilayer and therefore require a carrier protein to assist. The protein carriers are within the bilayer and they change shape when they come into contact with a specific molecule (i.e. Glucose). NO ENERGY IS REQUIRED.

Active transport; This moves substances for an area of low concentration to an area of high concentration against a concentration gradient. ENERGY IS NEEDED for this to occur. Specific carrier proteins are also required these can be called 'pumps'.

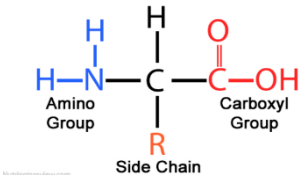
Proteins;

Proteins are made of long chains of amino acids, up to several hundred long. There are only 20 different amino acids and the combination of these 20 produce a wide range of complex proteins. Protein structures are held together with strong bonds called PEPTIDE bonds. The order of the amino acids determines the structure and how it works.

All amino acids have the same structure with one variation on the R group.

Contains; Hydrogen, oxygen,

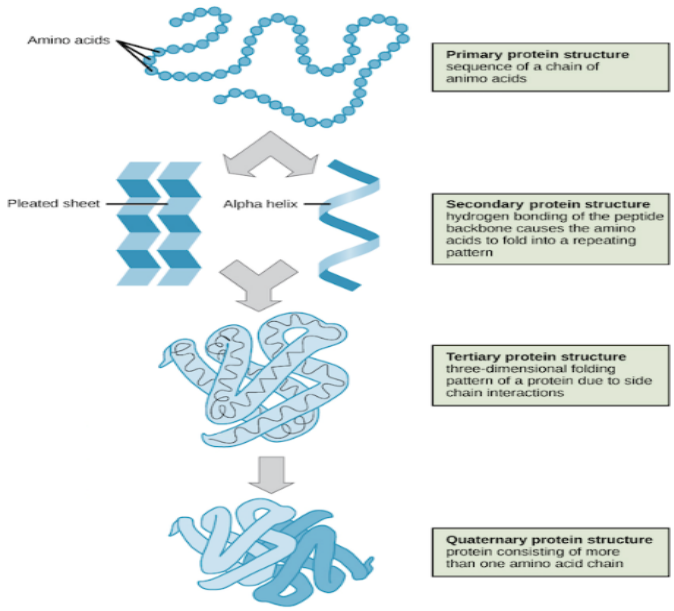
Nitrogen and carbon.



Proteins structure;

The order of the amino acids forms the PRIMARY STRUCTURE. The protein chain can then **coil** or **fold** into **pleats** which are held together by weak hydrogen bonds to for the SECONDARY STRUCTURE.

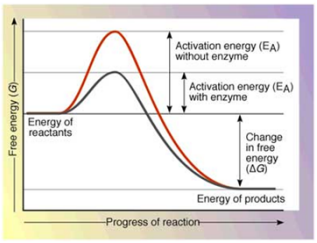
Enzymes have a further folding held together with stronger disulphide bonds. This is the TERTIARY STRUCTURE. If the structure is almost spherical it is called a **globular protein**.



Enzymes; Help to speed up biochemical reactions.

Metabolism is the sum of all the biochemical reactions that occur per second and a single chain of these reactions is called a metabolic pathway.

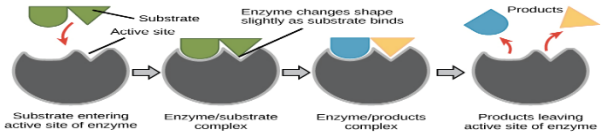
Enzymes are biological catalysts and increase the rate of reactions.



Reactions that release energy need an input energy to start. The input energy is called the ACTIVATION ENERGY. Enzymes reduce the activation energy.

Enzymes are proteins; enzymes are globular proteins with a specific order of amino acids that determines what the enzyme does.

Enzymes can be catabolic (break substrates down) or anabolic (build substrates up). Enzymes have a specific site into which the substrates can attach itself, this attachment site is called the **active site.** The active site is **complementary** to the shape of the substrate. Once they attach together they form the **enzyme substrate complex**. The substrate then breaks bonds or makes bonds (depending on the type of enzyme) and the product leaves the active site. The active site is now able to accept another substrate.



Denaturing enzymes; Enzymes have a specific tertiary shape held in place by weak hydrogen bonds and stronger disulphide bonds. These bonds can be broken by an increase in temperature (kinetic energy) or a change in pH (H^+ in acid or OH^- in alkali disrupt the bonds).

Useful enzymes; Digestive enzymes are catabolic, breaking down food into smaller molecules. Enzymes are also needed in DNA replication, building up molecules (DNA polymerase).

Questions;

What types of bond hold together the secondary structure? _____ The tertiary structure? _____

How many amino acids are there and what elements are found in them? _____

Explain why denatured enzymes will not function. _____

_____

What is activation energy? _____

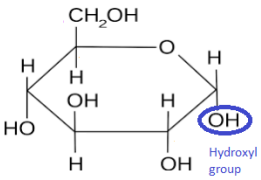
Carbohydrates;

Three elements make up the carbohydrate molecule – carbon, hydrogen and oxygen.

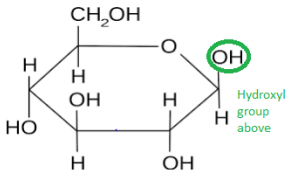
There are several types of carbohydrates;

Sugars; Small, sweet, water soluble molecules. Can be **monosaccharides** or **disaccharides**. Monosaccharides are single units from which disaccharides are built. **Glucose** and **Fructose** are monosaccharides and join together to form the disaccharide sucrose. The joining together of 2 monosaccharides occurs to release a molecule of **water** this is called a **condensation reaction.**

Glucose occurs in 2 forms alpha (α) glucose and beta (β) glucose.



Alpha glucose

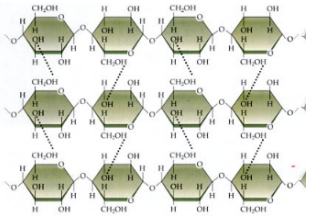


Beta glucose

Starch; A **POLYSACCHARIDE** (a large molecule –polymer, made up of monomers). Two different polysaccharides of glucose are used to make starch- **amylose** and **amylopectin**. Starch is insoluble so it is a good storage molecule in plants.

Cellulose; a polymer of glucose. Bonding is different in cellulose, molecules are bonded in a long straight line with **hydrogen** bonds between the strands. It forms **microfibrils** to provide strength to plant cell walls.

Cellulose

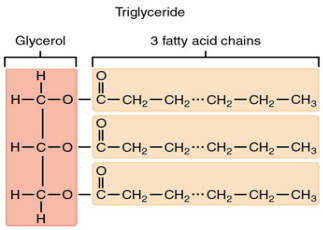


Amylopectin

Amylose

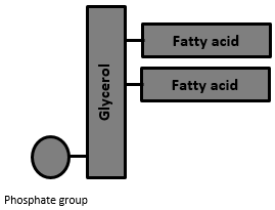
Lipids;

Three elements make up the lipid molecule – carbon, hydrogen and oxygen. Lipids are fats and oils, predominantly made up of a group of lipids called **triglycerides**. These contain a molecule of **GLYCEROL** with 3 **fatty acids**.



The fatty acid is a long chain of carbon atoms with an acid (-COOH) group. Hydrogen atoms are attached to the carbons by single bond. A single bond forms a **saturated** lipid. If there is a double bond then the lipid is **unsaturated**, many double bonds forms a **polyunsaturated** lipid.

Cell membranes are formed from phospholipid. They do not have 3 fatty acid chains but 2 fatty acid chains and a phosphate group.



Questions;

Describe the difference between a triglyceride and a phospholipid. _____

_____

Describe the difference between Starch and cellulose.

_____

_____

What bonds hold Cellulose microfibrils together? _____

Gas exchange in animals;

Lungs; Multi cellular organisms have evolved a **complex blood supply system** and a large gas exchange system (**lungs**). The lungs contain millions of tiny air sacs called ALVEOLI which are then folded to further increase the surface area of the lung.

The alveoli are further adapted by having a single flattened layer of **epithelial squamous cells** which reduces the diffusion distance increasing the speed of diffusion. Alveoli have a dense network of capillaries to move the blood away quickly, maintaining a steep diffusion gradient. The walls of the alveoli are fully permeable to dissolved oxygen and carbon dioxide.

Breathing/ventilation; The process of maintaining a high concentration of oxygen inside the lungs and getting rid of the waste product carbon dioxide. Ventilation increases he rate of diffusion.

Lungs are suspended in the airtight Thorax and any change in volume will affect the pressure in the thorax.

Gas exchange in plants;

Plants also have adaptations to allow gas exchange. The leaf is an organ that is adapted to allow the movement of water from the leaf and the diffusion of carbon dioxide into the leaf. The upper mesophyll layer contains Palisade cells which are packed with chloroplasts to absorb as much energy from the sun as possible for photosynthesis. The lower part of the mesophyll layer is the spongy mesophyll which contains air spaces to facilitated the diffusion of gases into the cells and out of the cells.

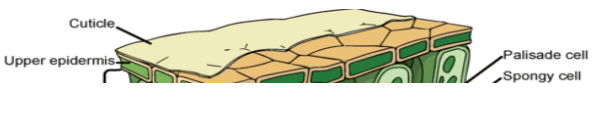
The upper epidermis is covered by a waxy cuticle to prevent water loss. The lower epidermis has a specialised pair of cells called the **GUARD CELLS**. The guard cells have an uneven thickening in the cell wall which causes the cell to bend and open up a hole in the lower epidermis called the **STOMA**. The stoma allows the water vapour to move out of the leaf into the environment (**transpiration**) and carbon dioxide to move into the leaf.

Transpiration; The movement of water from the root and out of the leaf is called the transpiration stream. Water passes into the root by osmosis and then moves through the root by 3 different processes;

- The symplast pathway; water moves from root cell to root cell through the cytoplasm.
- The apoplast pathway; water moves through the cell wall, not passing over the cell membrane, carrying minerals with it through a process called **MASS FLOW**.
- The vacuolar pathway; water moves from root cell to root cell via the cytoplasm and the vacuole.

Water moves out of the leaf by diffusion into the environment. The water moves from root to leaf through a specialised tube called the **xylem**. Water is pulled up the xylem due to an attraction force between the water particles causing a tension in the xylem (**Cohesion tension**) and the attraction between the water particles and the sides of the xylem vessel (**adhesion**).

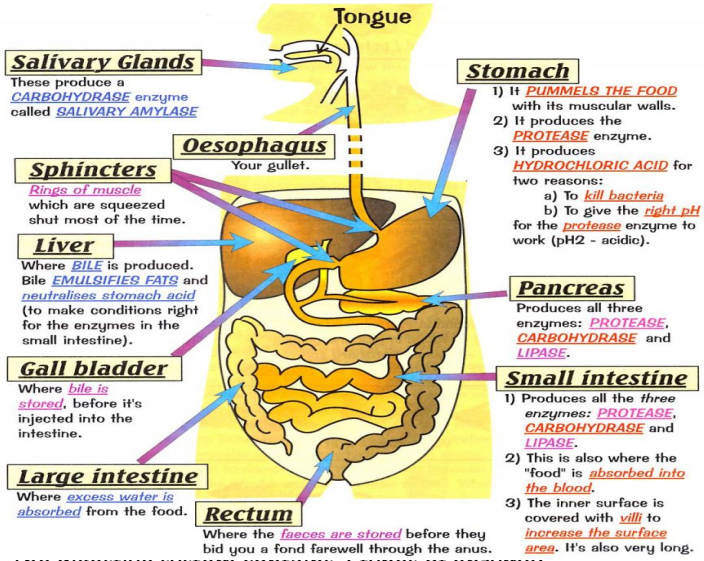
The second vessel in the plant is the **phloem** and this is responsible for **translocation**, the mass flow of substances from the leaf to the rest of the plant.



Other exchange surfaces;

Digestion; The human digestive system has 3 main functions;

- Mechanical breakdown of food
- Chemical breakdown of food
- Absorption of digested food particles into the blood stream.



The digestive system contains 3 types of enzyme;

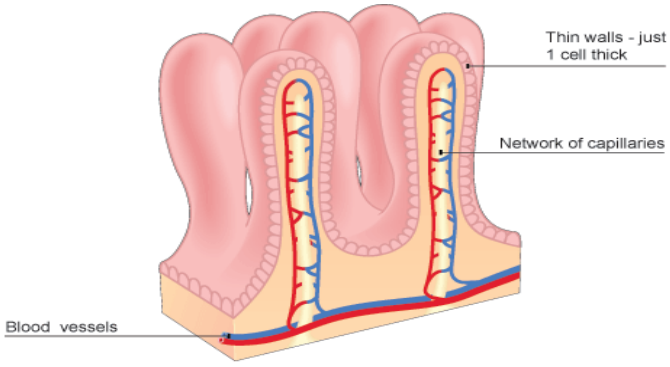
- **Carbohydrase** enzymes for breaking down complex carbohydrates into simple sugars. These are found in the mouth (amylase enzyme), the pancreas and the small intestine.
- **Protease** enzymes break down proteins into amino acids. These are found in the stomach (protease enzyme requires a pH 2 which is provided by the **hydrochloric acid**), the pancreas and the small intestine.
- **Lipase** enzymes breaks down lipids into fatty acids and glycerol. These are found in the pancreas and the small intestine.

Bile is an important chemical in digestion. Bile is made in the liver and stored in the gall bladder. It has 2 roles;

1) Makes the digested food, leaving the stomach, slightly alkali for enzymes to work in.
2) It emulsifies the lipids, breaking them up into small droplets to increase the surface area for lipase to digest.

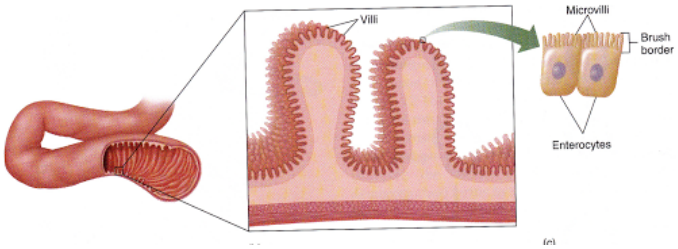
Other exchange surfaces:

All of the digested food is now small enough to pass through the wall of the small intestine into the blood stream.



As an exchange surface it displays the same characteristic adaptations as the lung; Large surface area to volume ratio, good blood supply and one cell thick.

Microvilli; the walls of the small intestine are highly folded into villi, to increase the SA:Vol. ratio. However, this can be increase further by each individual cell having further folds called microvilli.



Questions;

What are the features that makes a surface better adapted for exchange? _____

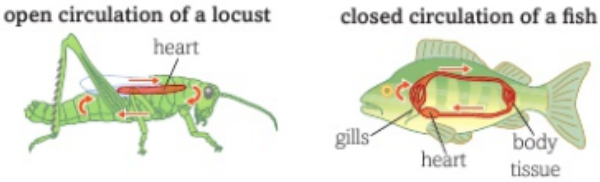
What is transpiration? _____

What is translocation? _____

The circulatory system and blood vessels;

Large multicellular organisms have a small surface area to volume ratio and have evolved a complex circulatory system to transport chemicals around the body, this is called the **CIRCULATORY SYSTEM**.

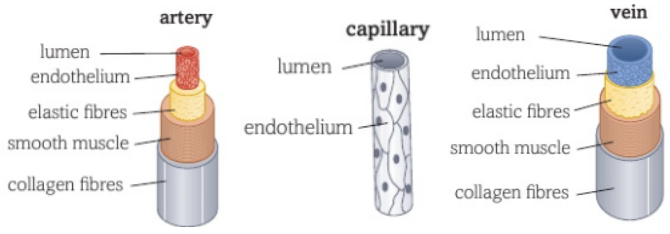
Some organisms such as flat worms can diffuse oxygen and glucose across their surface. Less active organisms such as insects may have a much more simplified circulatory system.



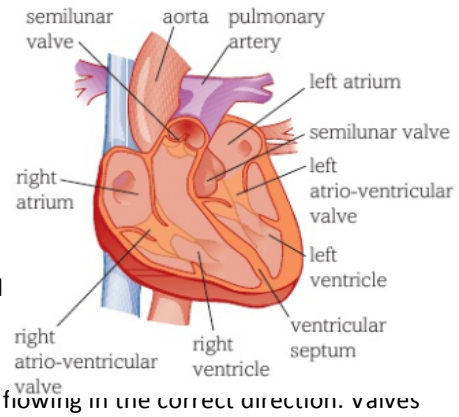
Fish have a more complex system were by the blood enters the heart once before being transported to the **systemic** system this is called a **single circulatory system**. Mammals have evolved a **double circulatory** system with a **pulmonary** and a **systemic** circuit.

The heart pumps the deoxygenated blood to the lungs **(pulmonary system**) to pick up oxygen and removes carbon dioxide. The oxygenated blood is then returned to the heart to be pumped out to the organs (**systemic system**).

The blood travels through 3 main types of blood vessels;
1) **The Arteries**; carry blood **away** from the heart. They have a thick layer of **elastic tissue** and **smooth muscle**. The elastic walls **stretch** when the heart contracts and the elastic tissue **recoils** to maintain the pressure.
2) **Capillaries;** These consist of a single layer of **endothelial cells**. The arteries subdivide **arterioles** which further divide into thousands of capillaries. The capillaries come into close contact with body cells providing a huge surface area to volume ratio and a short diffusion distance for the exchange of oxygen, glucose, carbon dioxide, urea and other substances.
3) **Veins**; The capillaries start to come back together forming **venules** and then veins. Veins carry blood back towards the heart. Blood is at a lower pressure and therefore do not need such a thick layer of elastic tissue or smooth muscle. The veins contain **valves** to prevent the blood flowing backwards.



The heart;



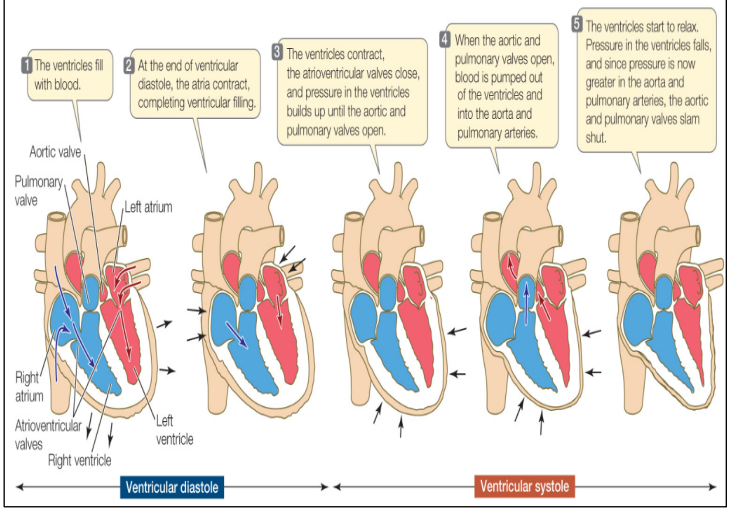
The heart has two separate pumps. The right side of the heart pumps blood to the lungs and the left side pumps blood to the body. Valves within the heart keep the blood flowing in the correct direction. Valves open and close in response to the changes of pressure inside the chambers.

The heart is made up of 4 chambers; the right **atria**, the right **ventricle**, the left **atria** and the left **ventricle**. The left side of the heart has a **thicker muscular wall** to create enough pressure to force the blood around the whole body.

The hearts contractions are initiated by a cluster of specialised cells called the **SINO-ATRIAL NODE** or the **PACEMAKER**. These cells send out electrical impulses at regular intervals.

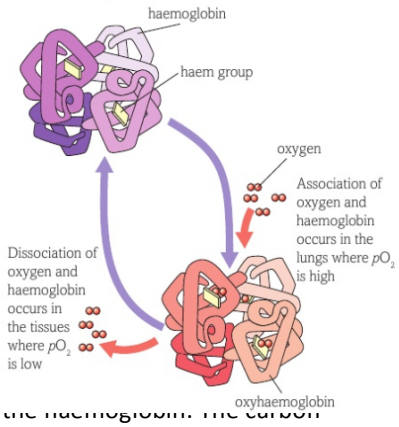
The coronary arteries supply the muscle in the heart with blood.

The cardiac cycle; This is the sequence of events that occur in a single heartbeat.



The blood;

Blood is made up of 4 different components;
1) **Plasma**; the liquid part of blood that transports the cells, dissolved substances and thermal energy.
2) **Platelets**; cell fragments responsible for clotting of the blood.
3) **White blood cells**; there are many different white blood cells all responsible for protecting the body from pathogens.
4) **Red blood cells** AKA **erythrocytes**; these are responsible for transporting oxygen to body cells. Erythrocytes contain a complex protein called **HAEMOGLOBIN**. Haemoglobin contains four iron ions each will bind to one oxygen. One haemoglobin can carry 4 molecules of oxygen (100% saturated) and becomes **OXYHAEMOGLOBIN**.



Due to the low availability of oxygen in the tissue and the high concentration of carbon dioxide, the oxygen will dissociate from the haemoglobin. The carbon dioxide from the respiring tissues makes the haemoglobin less able to 'hold on' to the oxygen so increases the rate at which the oxygen **dissociates**.

Questions;

1)What substance is picked up by the blood in the lungs?

_____

2) What is the name of the protein found in the erythrocyte?

_____

3) What metal ion is present in the protein? _____

4) What does it mean if the blood is said to be 'fully saturated'?

_____

_____

5) Which gas affects the oxygen binding properties of haemoglobin? _____

6) What is the term used to describe oxygen leaving the haemoglobin protein? _____

7) What is the name of the stage of respiration that is common to aerobic and anaerobic respiration? _____

8) What are the products of the first stage of respiration?

_____

9) Name the remaining 3 stages of aerobic respiration.

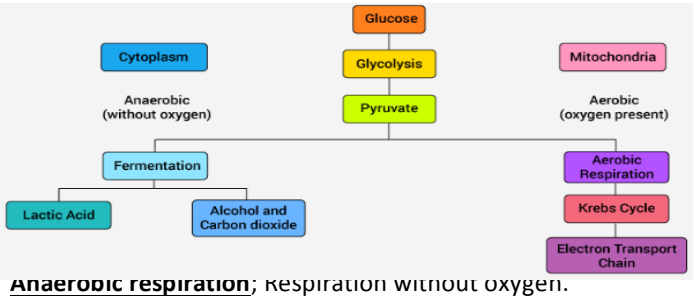
_____

_____

10) Name the molecule that is produced and will supply energy to other parts of the body. _____

Respiration;

Aerobic respiration; This occurs in the mitochondria of cells. It requires a number of small stages to break down **glucose** ($C_6H_{12}O_6$) to release a large amount of energy; **adenosine triphosphate** (ATP). The first stage is a stage called **GLYCOLYSIS**, this occurs in the cytoplasm and converts glucose into two 3 carbon molecules called **PYRUVATE**. Pyruvate is formed in both aerobic and anaerobic respiration, however in aerobic respiration the pyruvate passes into the matrix of the Mitochondria. Pyruvate then goes into the **link reaction** to form **acetyl CoA** which then passes into to the **Kreb cycle** with the oxidise products passing into **oxidative phosphorylation** to form **ATP** and waste products **carbon dioxide** and **water**.



Anaerobic respiration; Respiration without oxygen.
This form of respiration occurs **without oxygen**. Glucose is converted into pyruvate, through the process of **GLYCOLYSIS**, in the cytoplasm and is unable to pass into the mitochondria. The process of glycolysis releases small amounts of energy and over a short period of time it can keep the muscles working.

Anaerobic respiration in plants and yeast forms **carbon dioxide** and **alcohol**. Anaerobic respiration in animals forms **lactic acid**. The build-up of lactic acid in muscles must be broken down as the formation of the acid alters the pH and affects enzymes in the cells, slowing down reactions. As the lactate ions build up in the muscles this causes pain called **fatigue**. The oxygen required to convert the lactate ions back to pyruvate is called the **oxygen debt**.

Questions continued….

11) Define the term anaerobic respiration _____

_____

12) Write a word equation for;

a) anaerobic respiration in plants and yeast

_____

b) anaerobic respiration in mammals

_____

13) What is the oxygen debt? _____

_____

14) Why can a person not anaerobically respire for a long time?

_____

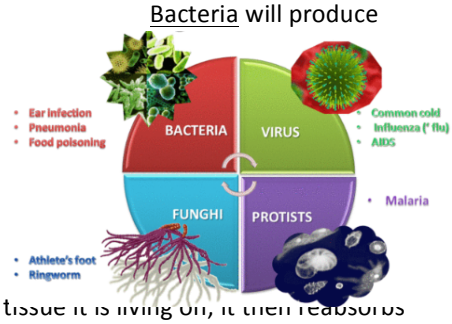
_____

Disease;

Disease can be **communicable** and **non-communicable**.

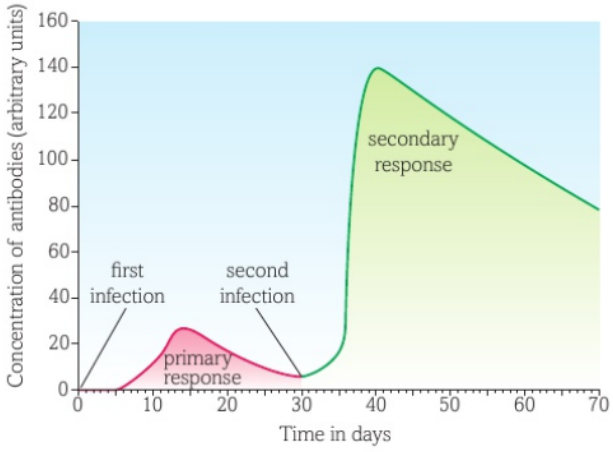
Non-communicable disease are disease's which cannot be directly passed for person to person. These include cancer, heart disease, diabetes and Alzheimer's.

Communicable disease are disease which can be transmitted from organism to organism. These are caused by **PATHOGENS** such as **VIRUSES**, **BACTERIA**, **FUNGI** and **PROTISTS**.



Bacteria will produce enzymes to digest the tissue it is living on, it then reabsorbs the digestive products. Protists use a host to complete an important part of its life cycle and will damage the hosts cells/organs in the process.

If the first lines of defence do not prevent the pathogen entering the body, then the bodies defence systems will be activated. All cells have a unique protein structure (**ANTIGEN**) identifying it as not self and activating the **immune system**. White blood cells will respond in different ways. First the **MONOCYTES** and **MACROPHAGES** (types of phagocyte) identify the pathogen as 'foreign'. These cells will **engulf** the pathogen and destroy it. Macrophages do not destroy all of the pathogen, it retains the antigen of the pathogen and '**presents**' it on its own surface. This is now an **ANTIGEN PRESENTING CELL** and initiates the next round of specific white blood cells. The **LYMPHOCYTES** now have 3 jobs, track down and destroy the pathogens (**T Lymphocytes**), produce antibodies (**B Lymphocytes**) and make **memory cells** to produce antibodies quickly if the pathogen enters the body again in the future.

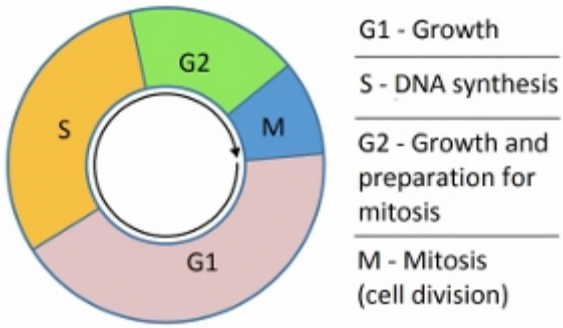


Primary and secondary response to infection.

Risk factors;

A risk factor is something that will **increase the chance** of becoming ill. Risk factors do not always lead to the disease, just increase the risk. Some risk factors are unavoidable such as genetic risk factors; genetic predisposition to producing high quantities of cholesterol, having high blood pressure or carrying the **BRCA** gene which increase the risk of breast cancer.

Other risk factors are avoidable such as; smoking, drinking alcohol, unprotected sex, high fat or high salt diet. Some risk factors (**carcinogens**) can cause DNA to mutate and cause cells to go into uncontrolled cell growth.



DNA and protein synthesis;

DNA is a complex chemical, found in the nucleus of eukaryotes and in the cytoplasm of prokaryotes. DNA is made up of; **pentose sugar**, **phosphate** and **nitrogenous bases** forming a **NUCLEOTIDE**.

There are 4 different nitrogenous bases;

A= Adenine

T= Thymine

C= Cytosine

G= Guanine

Complementary pair;

A pairs with T

C pairs with G

The bases pair up in the formation stated above. They are held together by **hydrogen bonds**. The two strands run in opposite directions causing the molecule to spiral forming a **DOUBLE HELIX**.

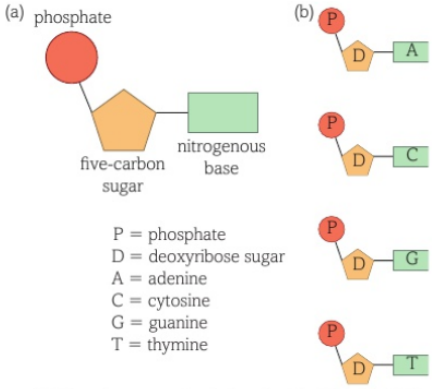


Figure 1 (a) General structure of a single nucleotide. (b) The four DNA nucleotides.

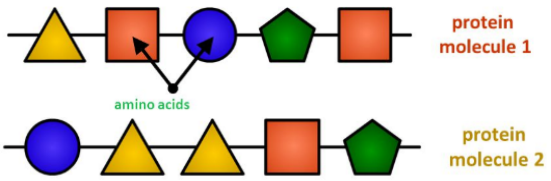
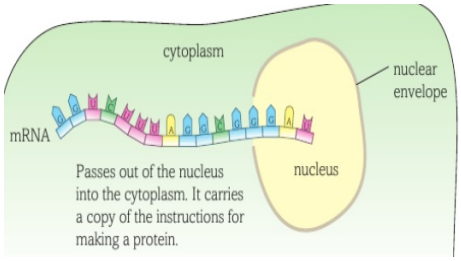
DNA controls the production of proteins. A section of DNA that codes for a protein is called a **gene**. Proteins are made up of a string of **amino acids**, each protein has a different number and order of amino acids. The proteins also have different bonds which holds the molecule in a unique shape which means all proteins have a different function.

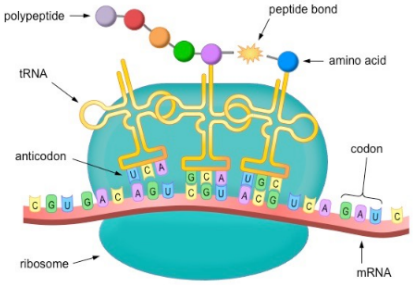


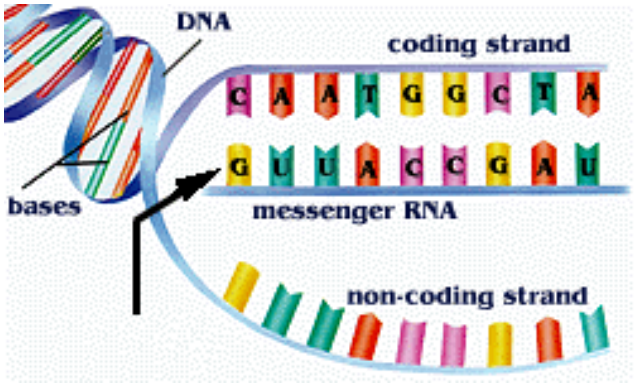
Different combinations of amino acids make different proteins.

Prote asm, carried out by **RIBOSOMES**. When a protein is required then the gene has to be copied producing a molecule called **messengerRNA (mRNA)**. mRNA is small enough to pass out of the nucleus into the cytoplasm. mRNA is a template, containing nucleotides and bases. The nucleotide on the mRNA will line up with the **complementary base**. However, on RNA there is no Thymine, RNA will have the base **URACIL** (**U**).

3



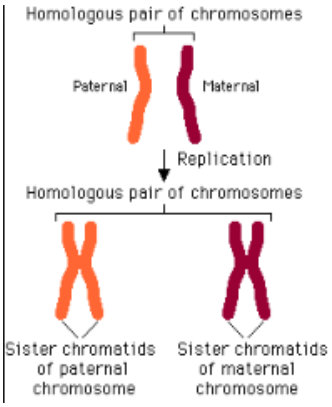




Genetics and cell division;

The DNA molecule contains thousands of genes along its length. The DNA molecule is wound up into a chromosome. Each body cell in a human contains **23 pairs of chromosomes (diploid number)**, one from mother and one from father. These pair up forming a **homologous pair**, both the **same size** and containing the **same genes** (these genes can be different **alleles**). A chromosome is often seen as an X shaped molecule. The X shape is actually one chromosome attached to an exact copy of itself (2 **CHROMATIDS**). They are joined together by an attachment called a **centromere.** In preparation for **cell division** the chromosome will make a copy of itself. All damaged tissue and cells are replaced by a process of cell division called **MITOSIS**. Mitosis is also seen in **asexual reproduction,** the offspring are **genetically identical** to the parent.

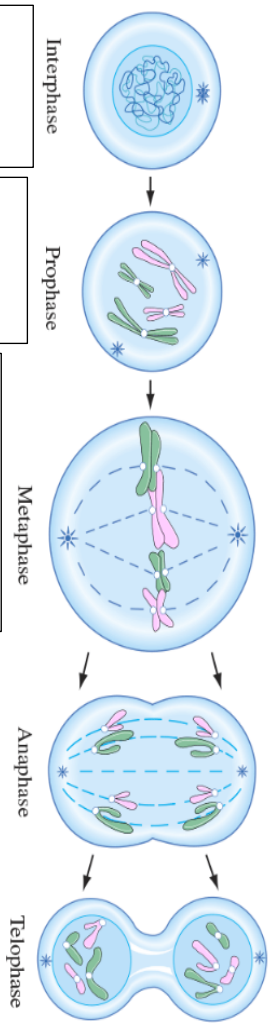
Mitosis cell division;



Interphase; DNA molecules are indistinct in the nucleus. They replicate their DNA, attaching at the centromeres.

Prophase; The DNA becomes **supercoiled** and **compact** and can now be seen under a light microscope. It has the X shape.

Metaphase; the nuclear membrane breaks down, the chromosomes line up along the **equator** of the cell and **spindle fibres**, produced by the **centrioles**, attach to the chromosomes.



Anaphase; The **spindle fibres** pull the **centromere** apart and the **chromatids** separate and are dragged to the poles of the cell.

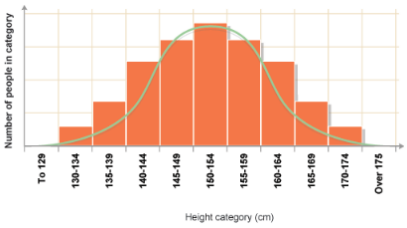
Telophase; A **nuclear envelope** forms around each set of **chromatids** and the **cytoplasm divides** forming 2 genetically identical cells.

Variation and evolution;

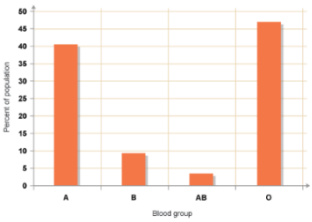
Due to the mechanisms used to produce haploid cells through meiosis, **genetic variation** occurs. Organisms of the same species show some variation due to alleles. There are 2 types of variation;

- **Genetic variation**; passed from parent to child (blood group, eye colour).
- **Environmental variation**; caused by the environment (scars, accents, freckles)

Some variation can be due to a **combination of both** genetic variation and environmental variation (intelligence, height and weight).

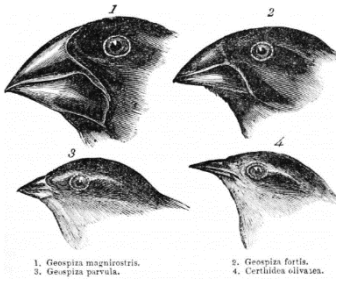


Some **characteristics** fall into the category of **continuous variation** whereby there is a large range in variations (height and weight).



Other characteristics fall into a few distinct categories such as blood type, colour, tongue rolling; this is called **discontinuous variation**.

Sometimes a variation may lead to a characteristic that helps the organism to **survive** and be **better adapted** to its environment. The variation may be that the animal is slightly fast or better camouflaged. This slight difference within the species will allow the individual to **compete** better, **survive**, **breed** and potentially **pass on the genetic variation** to it's offspring. This is called **Natural selection**. **Evolution** can occur through natural selection. **Gradual changes over millions of years** can ultimately lead to the formation of a **new species**.

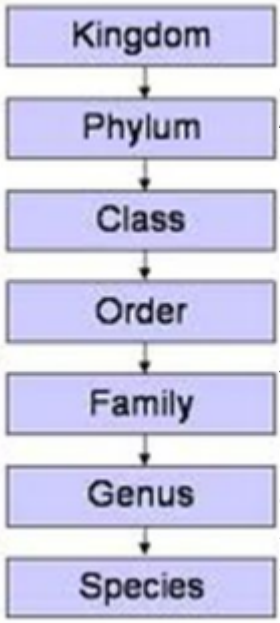


as antibiotic-resistant bacteria. Darwin noticed that the finches - songbirds - on the different islands in the Galápagos were fundamentally similar to each other, but showed wide variations in their size, beaks and claws from island to island. For example, their beaks were different depending on the local food source. Darwin concluded that, because the islands are so distant from the mainland, the finches that had arrived there in the past had changed over time.

Classification;

King Prawn Curry Or Fat Greasy Sausages.

Developed by Carl Linnaeus in the 18th century, it was a method of sorting, grouping and naming different groups of organisms.



Organisms were grouped into divisions based on characteristics they had in common. The five kingdoms are; **Animalia, Plantae, Fungi, Prokaryotes, Protoctists**. The kingdoms then divide into **Phylum**; in Animalia these are; Cnidaria (**invertebrates**), Chordata (**vertebrates)**, Arthropods, Molluscs and Echinoderms.

In animals the vertebrate's phylum further splits into Mammalia (Mammals), Fish, Birds, Amphibians and Reptiles.

Order, Genus and species further classifies the organisms. The Genus and species names are always written in Latin and italics. The genus name has a capital letter and the species is lower case.

A species was classified as a group of organisms that look very similar to each other and can reproduce to form fertile offspring.

Technology has advanced and organisms can now be classified on a genetic level using base sequence, proteins and enzymes in common and growth during embryonic stage.

The Three Domains; Taxonomic ranking was altered in the 1970's with the introduction of the domains before kingdom. It was further clarified in the 1990's with better understanding of cellular structure. **Archaea** are prokaryotic cells, **Bacteria** (even though bacteria are prokaryotic cells just like Archaea, their cell membranes have a different composition) and **Eukarya** (eukaryotes).

Questions;

What type of variation can be displayed as a distribution curve?

_____

What type of variation can be displayed on a bar chart?

_____

Describe Natural selection. _____

_____

_____

_____

_____

What are the 3 domains? _____

What method did Linnaeus use to group organisms? _____

_____

What newer methods are now used? _____

_____

Define species. _____

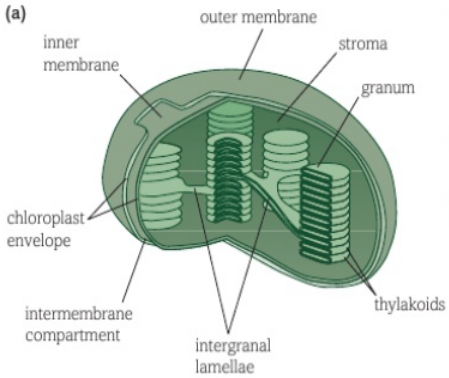
Photosynthesis;

Photoautotrophs are organisms that produce their own food with the use of **solar energy**. They are the source of chemical energy for other organisms within a food chain.

The general equation for photosynthesis is:

$$6CO_2 + 6H_2O + \text{energy from photons} \xrightarrow{\text{chlorophyll}} C_6H_{12}O_6 + 6O_2$$

Photosynthesis is and **endothermic** reaction requiring the energy to initiate it. A special organelle in the plant cell called the **CHLOROPLAST** contains a chemical called **CHLOROPHYLL**. The chloroplast has an inner and outer membrane called the



envelope. Inside the chloroplast are flattened sacs called **GRANA**. The grana stack up to form **THYLAKOIDS**. The chemical, chlorophyll is embedded in the Thylakoid membrane in **PHOTOSYSTEMS.**

The photosystems contain different **photosynthetic pigments** which absorb different wavelengths of light. A fluid filled matrix called the **STROMA** surrounds the grana and contains **enzymes** and **DNA** for protein production within the chloroplast.

Photosynthesis occurs in two stages;

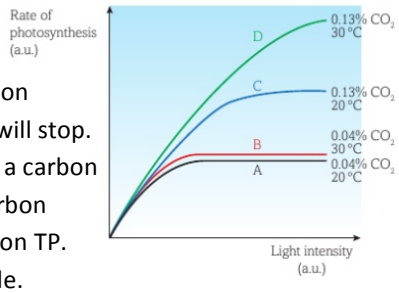
- **The Light dependent stage (LDS)**; this uses light energy and water to provide **hydrogen ions** and **electrons**, which are moved through electron carriers, to produce **oxygen** and **reduced NADP** which can pass into the next phase.
- **The light independent stage (LIS) or CALVIN CYCLE**; the Calvin cycle uses inorganic carbon dioxide gas to produce organic glucose. A five carbon compound called **Ribulose bisphosphate** accepts one carbon from the carbon dioxide with the help of an enzyme, **RuBisCo**. This forms and unstable 6 carbon compound which dissociates into two 3 carbon molecules called glycerate-3-phosphate (GP) which then accepts a hydrogen ion from the reduced NADP (brought in from the light dependent stage) to make 2 molecules of triose phosphate (TP). TP can then be synthesised into other sugars or used to synthesis amino acids, fatty acids and glycerol.

Limiting factors and Photosynthesis;

Factors that can affect the rate of photosynthesis are called limiting factors. These can be the raw materials of photosynthesis (**carbon dioxide** and **water**), **Light intensity** or factors that affect enzymes responsible for photosynthesis (**temperature** and **pH**).

Water stress; water does not generally limit photosynthesis since it is required in other cellular reactions the plant, turgidity, transpiration stream and cooling is usually dead before water is at a low enough level to affect photosynthesis.

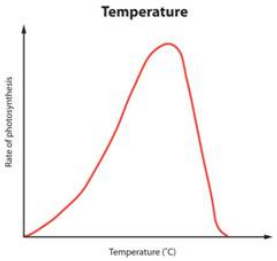
Carbon dioxide;



Without the presence of carbon dioxide then photosynthesis will stop. Ribulose bisphosphate needs a carbon from CO_2 to become the 6 carbon molecule and then the 3 carbon TP. Without TP no glucose is made.

Light intensity; Light is required to provide photons of energy in the LDS. Light can also cause the stoma to open in the leaf bringing about transpiration.

Temperature;



At lower temperatures the rate of reaction is slow due to the molecules and enzymes having less **kinetic energy** and therefore fewer collisions per second. As the temperature increases, the molecules gain more kinetic energy and collisions per second increase as does the reaction rate. However, these reactions are reliant upon enzymes. Enzymes have a specific structure to allow them to carry out the specific function. As the temperature increases then hydrogen and disulfide bonds, holding the tertiary structure, will break and the enzymes active site changes shape (**DENATURES**) and the enzyme can no longer catalyse the reaction.

pH; Similar to temperature, enzymes work best in particular pH's. If the pH alters then bonds break and the enzyme denatures.

Questions; Define photoautotroph. _____

Where in the chloroplast are the photosynthetic pigments found? _____

_____

What reactant of photosynthesis is broken down in the light dependent stage? _____

What reactant of photosynthesis is used in the light independent stage? _____

What effect does increasing temperature have on the rate of photosynthesis? _____

_____
